Semi-Analytic Method in Fast Evaluation of Thermal Management Solution in Energy Storage System

Ya Lv

Abstract-This article presents the application of the semianalytic method (SAM) in the thermal management solution (TMS) of the energy storage system (ESS). The TMS studied in this work is fluid cooling. In fluid cooling, both effective heat conduction and heat convection are indispensable due to the heat transfer from solid to fluid. Correspondingly, an efficient TMS requires a design investigation of the following parameters: fluid inlet temperature, ESS initial temperature, fluid flow rate, working c rate, continuous working time, and materials properties. Their variation induces a change of thermal performance in the battery module, which is usually evaluated by numerical simulation. Compared to complicated computation resources and long computation time in simulation, the SAM is developed in this article to predict the thermal influence within a few seconds. In SAM, a fast prediction model is reckoned by combining numerical simulation with theoretical/empirical equations. The SAM can explore the thermal effect of boundary parameters in both steady-state and transient heat transfer scenarios within a short time. Therefore, the SAM developed in this work can simplify the design cycle of TMS and inspire more possibilities in TMS design.

Keywords—Semi-analytic method, fast prediction model, thermal influence of boundary parameters, energy storage system.

I. INTRODUCTION

WITH increased demand of energy resources, traditional energy solution unavoidably induces non-neglected ecology issues, such as smog and killed-nature lives. Therefore, renewable energy is up-rising in the market, as shown in Fig. 1 [1] in which Denmark is leading development of renewable energy, and other countries are on the way of catching up. To enhance and complement application of Wind Energy and Solar Energy, ESS is indispensable by balancing influence of intermittent weather conditions. Moreover, ESS plays important role in Microgrids development, as displayed in Fig. 2 [2]. ESS can function to shave peak and regulate frequency of grid, as well as provide uninterrupted power supply or black-start at off-grid situations.

Mainstream ESS is composed of Lithium-ion battery cells. Lithium-ion battery's performance is represented by major five indicators: capacity, working c-rate, cycle life, cost and safety. They are influenced by many factors, among which temperature is the most crucial. Lithium-ion battery favors temperature range of 15 °C to 35 °C, too low or too high temperature shortens battery lifecycle by increasing internal resistance, correspondingly, degrades capacity and weakens safety [3], [4]. As a result, an effective TMS is significant in maintaining of battery's performance and extension of

Ya LV is with the Durapower Group, Singapore (e-mail: laylaneylv@gmail.com).

battery's lifecycle. TMS exploration involves a number of trials, where the SAM is needed to simplify design cycle and inspire more design possibilities.

II. METHODOLOGY

A module design of ESS is investigated in this work, in which heat generated by battery cells will be conducted and spread to cooling surface, to be taken away by the flowing fluid, as shown in Fig. 3. The thermal network [5] of this ESS is described in Fig. 4, in which two major thermal barriers are indicated, one is between battery cells and cooling surface R_{th1} , the other is between cooling surface and flowing fluid R_{th2} . In this work, we assume there is thermal interfacial materials and heat spreading structure in the module, so R_{th2} . dominates the module's thermal performance.

Fig. 3 Lithium-ion battery module

Fig. 4 Thermal network of fluid-cooling ESS

In the studied battery module, change of \dot{m}_{fluid} affects heat convection between fluid and cooling surface, namely, R_{th2}. In heat transfer, R_{th2} can be calculated with empirical equations, as shown in (1)-(8) [6] in which Nu is the ratio of fluid conduction thermal resistance to fluid convective thermal resistance at solid-fluid boundary, Re is calculated with fluid velocity and flow duct characteristic length, Pr is determined by fluid type. Via the equations, R_{th2} can be calculated by obtaining h_{conv} from Nu, before which, the Re is estimated for selecting solving empirical equation. Consequently, there will be an updated R_{th2} when \dot{m}_{fluid} varies.

The average Nu _ empirical equations:

$$Nu = 0.664 \, Re_L^{0.5} P r^{1/3}, \qquad Re < 5 * 10^5 \tag{1}$$

 $Nu = 0.037 Re_L^{0.8} Pr^{1/3}, 5 * 10^5 \le Re \le 10^8, 0.6 \le Pr \le 60$ (2)

$$Nu = \frac{h_{conv}D}{k_{fluid}}, Re = \frac{UD}{v_{fluid}}$$
(3)

$$R_{th2} = 1/(h_{conv}A_{cooling}) \tag{4}$$

$$\dot{m}_{fluid} = \rho_{fluid} U A_{cross-section} \tag{5}$$

$$\frac{R_{th2-1}}{R_{th2-0}} = \frac{h_{conv-0}}{h_{conv-1}} = \frac{Nu_0}{Nu_1}$$
(6)

$$\frac{Nu_0}{Nu_1} = \left(\frac{Re_0}{Re_1}\right)^{0.5} = \left(\frac{\dot{m}_{fluid-0}}{\dot{m}_{fluid-1}}\right)^{0.5}, \qquad Re < 5 * 10^5$$
(7)

$$\frac{Nu_0}{Nu_1} = \left(\frac{Re_0}{Re_1}\right)^{0.8} = \left(\frac{\dot{m}_{fluid-0}}{\dot{m}_{fluid-1}}\right)^{0.8}, \quad 5 * 10^5 \le Re \le 10^8 \quad (8)$$

III. STEADY-STATE ANALYSIS

Steady-state heat transfer is non-relevant with time or heat capacity. Thus, (9)-(13) [7] can be applied to describe the heat transfer in the battery module, the heat power will be transferred to flowing fluid for its thermal absorption.

$$q_{tot} = \frac{T_{hottest \ cell} - \overline{T_{fluid}}}{R_{tot}^{max}} = \frac{T_{coldest \ cell} - \overline{T_{fluid}}}{R_{tot}^{min}}$$
(9)

$$q_{tot} = \dot{m}_{fluid} * C_{fluid} * (T_{fluid}^{outlet} - T_{fluid}^{inlet})$$
(10)

$$R_{tot} = R_{th1} + R_{th2} \tag{11}$$

$$\overline{T_{fluid}} = (T_{fluid}^{inlet} + T_{fluid}^{outlet})/2$$
(12)

$$\Delta T_{cells}^{max} = T_{hottest\ cell} - T_{coldest\ cell}$$
(13)

By correlating numerical simulation with theoretical/ empirical equations, the SAM can forecast thermal influence at varied input parameters. Fig. 5 shows the SAM flowchart in steady-state analysis, in which thermal simulation of battery module can be conducted at input parameters: $T_{fluid}^{inlet}, \dot{m}_{fluid},$ q_{tot} . Then, R_{tot}^{max} , R_{tot}^{min} will be calculated from simulation results based on (9). If \dot{m}_{fluid} changes, R_{tot}^{max} , R_{tot}^{min} need to be updated on basis of (7) or (8). According to (9)-(13), the thermal effect of varied $T_{fluid}^{inlet}/\dot{m}_{fluid}/q_{tot}$ can be predicted by updating $T_{hottest cell}$, ΔT_{cells}^{max} in battery module.

A. Steady-State Case Study

In this steady-state analysis, seven cases were studied, as shown in Table II in which a reference case was simulated to be used in SAM, the other six cases were investigated via simulation and SAM respectively. It is found in Table II that: T_{fluid}^{inlet} changes in case1 and 2, \dot{m}_{fluid} varies in case3 and 4, case5 and 6 reflects change of q_{tot} . In Table III,, the R_{tot}^{max} , R_{tot}^{min} obtained from simulation results of reference case can be found. Table IV lists comparison of updated R_{tot}^{max}, R_{tot}^{min} between simulation and SAM based on \dot{m}_{fluid} variation in case3 and 4. Comparison of $T_{hottest cell}$, ΔT_{cells}^{max} between simulation and SAM on six studied cases is indicated in Table V.

B. Steady-State Results and Discussion

As is seen in Table IV, the relative difference between simulation and SAM is < 3% for R_{tot}^{max} , < 7% for R_{tot}^{min} . This is due to the application of empirical equations (1) and (2) in updating of R_{tot} , correspondingly, we can find relative difference of 10.7% for ΔT_{cells}^{max} in case3, as shown in Table V.

But the relative difference between simulation and SAM in other cases is < 3%, as listed in Table V. Therefore, a good matching between simulation and SAM can be found in this steady-state analysis. Compared to tedious simulation work and consumable time, the SAM can instantly predict thermal effect from variation of input parameters in battery module.

IV. TRANSIENT ANALYSIS

Different from steady-state analysis, t, T_{cell}^0, C_{thi} are becoming influential factors in transient heat transfer. So, energy equivalent equation is applied to describe the heat transfer comprehensively, as shown in (17)-(19). In this transient analysis of battery module, we assumed that heat power generated by battery cells is divided into two parts, one part is thermally absorbed by battery cells, the other part is to flowing fluid via cooling surface. transferred Correspondingly, an approximate thermal network can be generated, as shown in Fig. 6.

Fig. 6 Approximate thermal network in transient analysis of fluidcooling ESS

In the SAM, numerical simulation together with theoretical and empirical equations contributes to the thermal prediction. Fig. 7 shows the SAM flowchart in transient analysis, in which thermal simulation of battery module can be conducted at six known parameters $T_{fluid}^{inlet}, \dot{m}_{fluid}, q_{tot}, t, T_{cell}^0, C_{thi}$. Then, R_{th2}^{sim} will be obtained from simulation results based on (14)-(16). When \dot{m}_{fluid} changes, R_{th2}^{sim} will be updated on basis of (7) or (8). Next, the iterative prediction model will work by assuming T_{fluid}^{outlet} , $\overline{T_{fluid-0}}$. The assumed T_{fluid}^{outlet} can be used to calculate T_{cell}^t via (17)-(19), and q_{flow}^t will be calculated via (19). Thereafter, $\overline{T_{fluid-itr}}$ can be obtained from (20) and (21). The difference between $\overline{T_{fluid-itr}}$ and $\overline{T_{fluid-0}}$ will be controlled by iterating the whole prediction process until it falls below a threshold. This is when the predicted T_{cell}^t can be gained. Because of the iterative prediction process in SAM in transient analysis, only T_{cell}^{t} is forecasted to represent

the thermal effect from change of input parameters.

Fig. 7 SAM flow chart in transient analysis

Simulation Calculation Equations (SCE):

$$R_{th2}^{sim} = (T_{cell}^{t-sim} - \overline{T_{fluid-sim}})/q_{flow}^{t-sim}$$
(14)

$$q_{flow}^{t-sim} = (q_{tot} * t - E_{cell}^{sim})/t$$
(15)

$$E_{cell}^{sim} = m_{cell} * C_{cell} * \left(T_{cell}^{t-sim} - T_{cell}^{0}\right)$$
(16)

Approximate Energy Equivalent Equations (AEEE):

$$q_{tot} * t \approx E_{cell}^t + q_{flow}^t * t \tag{17}$$

$$E_{cell}^t = m_{cell} * C_{cell} * (T_{cell}^t - T_{cell}^0)$$
(18)

$$q_{flow}^{t} = (T_{cell}^{t} - \overline{T_{fluid}}) / R_{th2}$$
(19)

Fluid Transfer Equation (FTE):

$$q_{flow}^{t} = \dot{m}_{fluid} * C_{fluid} * (T_{fluid}^{outlet} - T_{fluid}^{inlet})$$
(20)

$$\overline{T_{fluid}} = (T_{fluid}^{outlet} + T_{fluid}^{inlet})/2$$
(21)

B. Transient Results and Discussion

As is shown in Table VIII, the relative difference between simulation and SAM is < 8% for R_{th2} . This is due to the application of empirical equations (1) and (2) in updating of R_{th2} . In Table IX, it can be found that the relative difference of $T_{hottest cell}$ between simulation and SAM in all 12 cases is < 3%. Therefore, a good matching between simulation and SAM is verified in transient analysis of battery module. Given above comparison results between simulation and SAM, it is confident to predict thermal influence from varied input parameters in battery module.

V.CONCLUSION

The present work introduces SAM applied for predicting thermal influence of varied factors and optimizing TMS in ESS. The SAM is developed on basis of numerical simulation and theoretical/empirical equations. In this work, both steady-state and transient heat transfer were analyzed, thermal effect of varied input parameters was investigated via different cases. In steady-state analysis, an excellent matching was found in six cases between simulation and SAM on predicting $T_{hottest \ cell}$, ΔT_{cells}^{max} in battery module. In transient analysis, an excellent consistency was verified in 12 cases between simulation and SAM on forecasting $T_{hottest \ cell}$ in battery module.

Compared to all-cases numerical simulation, the SAM only needs one simulation of reference-case to be built up in both steady-state and transient scenarios. Compared to consumable computation resources and long computation time in numerical simulation, the SAM can predict thermal impact from changeable boundary parameters within a few seconds. In all, the SAM can be applied to improve TMS design efficiency and predict thermal performance of ESS within short time.
