Feeder Reconfiguration for Loss Reduction in Unbalanced Distribution System Using Genetic Algorithm

Ganesh. Vulasala, Sivanagaraju. Sirigiri, Ramana. Thiruveedula

Abstract—This paper presents an efficient approach to feeder reconfiguration for power loss reduction and voltage profile imprvement in unbalanced radial distribution systems (URDS). In this paper Genetic Algorithm (GA) is used to obtain solution for reconfiguration of radial distribution systems to minimize the losses. A forward and backward algorithm is used to calculate load flows in unbalanced distribution systems. By simulating the survival of the fittest among the strings, the optimum string is searched by randomized information exchange between strings by performing crossover and mutation. Results have shown that proposed algorithm has advantages over previous algorithms The proposed method is effectively tested on 19 node and 25 node unbalanced radial distribution systems.

Keywords—Distribution system, Load flows, Reconfiguration, Genetic Algorithm.

I. INTRODUCTION

POWER distribution systems typically have tie and sectionalizing switches whose states determine the topological configuration of the network. The system configuration affects the efficiency with which the power supplied by the substation is transferred to the load. Power companies are interested in finding the most efficient configuration, the one which minimizes the real power loss of their three-phase distribution systems. It was estimated that distribution systems cause a loss of about 5–13% of the total power generated [1] in developing countries.

In [2]-[3] a branch exchange method was used in which approximate formulae provide the change in loss due to feeder reconfiguration. Shirmohammadi and Hong [4] proposed a technique in which the switches were opened one by one beginning from a fully meshed system, based on an optimal flow pattern. Goswami and Basu [5] proposed an algorithm based on optimal flow pattern, of a single loop, formed by closing a normally open switch, and the switch with minimum current was opened. Taylor and Lubkeman [6] developed an

expert system using heuristic rules to shrink the search space for reducing the computation time. Glaomocanin [7] used a quadratic programming technique to solve the reconfiguration problem. Wagner et al. [8] proposed a linear programming method and a heuristic search method. Borozan et al. [9] presented a method similar to that of [2]-[3], for solving reconfiguration problem. Compensation based power flow method was used to obtain power flow solution for meshed system. A survey on reconfiguration was presented in [10]. Sarfi et al. [11] developed a method based on partitioning the distribution system into group of load buses, such that the line section losses between groups of nodes were minimized.

Roytelman et al. [12] presented a heuristic-based two stage solution approach, in which weights were assigned to multi-objective functions. In [13]-[14], algorithms for distribution system switch reconfiguration and capacitor control have been proposed. McDermott et al. [15] proposed a constructive heuristic method that started with all switches open, and at each step, the switch that resulted in the least increase in the objective function was closed. Chen and Cho [16] presented an approach to derive optimal switching plan to achieve energy loss minimization, for short and long-term operation of distribution systems. Zhou et al. [17] proposed a heuristic approach for reconfiguration, which reduced operating cost over a specified time period. Schmidt et al. [18] formulated the problem as mixed integer, nonlinear optimization problem. Newton method is used to compute branch currents within the integer search.

In [19], a method was proposed to determine the configuration with minimum energy loss for a given period. In [20]–[23], solution strategies have been proposed for feeder reconfiguration using simulated annealing. Morton et al. [24] developed graph–theoretic techniques involving semi-sparse transformations of a current sensitivity matrix. In [25]–[31], different approaches were presented to obtain minimum loss configuration of the distribution system using genetic algorithm. Hsiao, Y.T [32] developed algorithms based on multi objective evolution programming method for feeder reconfiguration. A heuristic method for three-phase unbalanced systems was proposed in [33] based on approaches in [3, 4]. Wang et al. [34] proposed an algorithm to minimize loss and load balancing for a large-scale unbalanced system using network reconfiguration. In this method, explicit loss formulae were developed for determination of switching operations.

It can be seen from the literature heuristic based method has been proposed for the problem under consideration. Hence, there appears to be a need for developing a simple reconfiguration method using GA for unbalanced systems. In this paper, a GA is presented for reconfiguration of unbalanced distribution systems for loss minimization. A simple method for determining the open/closed states of sectionalizing and tie switches to achieve loss reduction is explained. The performance of proposed method is tested with two different unbalanced radial distribution systems consisting of 19 and 25 node unbalanced radial distribution systems.

In this work distribution system considered as three-phase three wire line sections and all of them are phase-symmetrical, but bus loads may not be equal for all phases. Therefore, the distribution network should be treated as unbalanced. The goal of this work describes a simple reconfiguration method for unbalanced radial distribution systems for loss minimization has been proposed, which is reasonably simple. The effectiveness of the proposed method has been compared with the methods of Shirmohammadi and Hong [4] and Goswami and Basu [5] in respect of switching and loss reduction.

II. PROBLEM FORMULATION LOSS MINIMIZATION

In the radial distribution system, each radial feeder is divided into load sections with sectionalizing switches and is connected to other feeders via several tie switches. The distribution systems loss minimum reconfiguration problem is to decide the position of sectionalizing switches to obtain the best minimum distribution losses with satisfying the following constraints. This problem can be formulated as

$$Minimize \ \ f = \sum_{j=1}^{nb} P_{loss \ j}^{abc} \tag{1}$$

where,

nb is the number of branches

$P_{loss \ j}^{abc}$ is the loss in branch j

Subject to the following constraints

i. Radial network constraint

Distribution network should be composed of radial structure considering operational point of view.

ii. Power source limit constraint

The total loads of a certain partial network cannot exceed the capacity limit of the corresponding power source.

$$P_s^{abc} \leq P^{max} \tag{2}$$

$$Q_s^{abc} \leq Q^{max} \tag{3}$$

iii. Voltage constraint

Voltage magnitude at each bus must lie with their permissible ranges to maintain power quality.

$$V_q^{min} \leq V_q^{abc} \leq V_q^{max} \tag{4}$$

iv. Current constraint

Current magnitude of each branch must lie within their permissible range.

$$I_j^{abc} \leq I_j^{max} \tag{5}$$

In the network reconfiguration problem the load flow study is required to calculate the overall real power loss for a given system configuration in order to rank it against other configurations.

A. Three phase Load flow

In a three phase unbalanced load flow of distribution system the following components are modeled by their equivalent circuits in terms of inductance, capacitance, resistance and injected current.

Conductors – Individual phase representation for both primary and secondary with capacitive line charging on primary conductor only.

Transformers – A general approach is recommended where by all transformer connections, including the common core transformer, are represented as individual transformers.

Capacitors – Capacitors are represented by their equivalent injected currents.

Loads – The unbalanced loads are basically considered because of single phase, two phase and unequal three phase loads which exist in different types viz. constant power, constant Impedance and constant current.

Shunt admittance and series impedance are represented by the actual phase quantities.

B. Forward- Backward Sweep Load Flow Method

There are several power flow methods based on forward/backward sweep technique. They may be classified as power summation methods and current summation methods. current summation method is used in this paper as it is more convenient and fast than power summation method because it uses only 'V' and 'I' instead of P and Q.

C. Backward Sweep

The purpose of the backward sweep is to update branch currents in each section, by considering the previous iteration voltages at each node. During backward propagation voltage values are held constant at the values obtained in the forward path and updated branch currents are transmitted backward along the feeder using backward path. Backward sweep starts from extreme end branch and proceeds along the forward path. Fig. 1 shows phase *a* of a three-phase system where lines between nodes *p* and *q* feed the node *q* and all the other lines connecting node *q* draw current from line between node *p* and *q*.
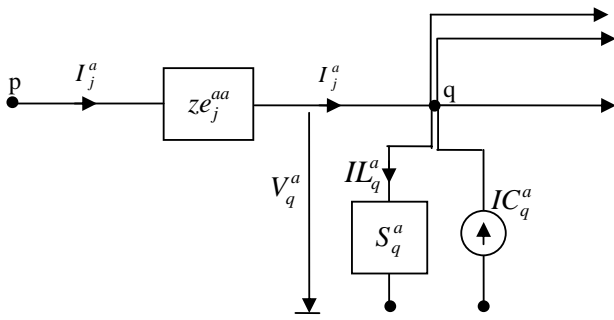

Fig.1. Single phase line section with load connected at node q between to phase 'a' and neutral n.

The parent branch current feeds the load at the qth node and the sub-laterals connected to the parent branch. This current can be calculated using Eqn. (6).

$$I_j^{abc^k} = IL_q^{abc^k} + \sum_{m \in M} I_m^{abc^k} + \sum_{m \in M} \left(Y_{sh_m}^{abc^k} \right)\left(V_{q_m}^{abc^{k-1}} \right) \quad (6)$$

Where

$Y_{sh_m}^{abc^k}$ is the half line shunt admittance of the branch in k^{th} iteration.

$I_j^{abc^k}$ is the branch current vector in line section j in k^{th} iteration.

$I_m^{abc^k}$ is the current vector in branch m before updating in k^{th} iteration.

$v_{q_m}^{abc^{k-1}}$ is the voltage vector of the branch m in $(k-1)^{th}$ iteration.

M represents the set of line sections connected to j^{th} branch If capacitor bank is placed at the receiving end of the branch then capacitor current should also be included.

D. Forward Sweep

The purpose of the forward sweep is to calculate the voltages at each node starting from the source node. The source node voltage is set as 1.0 per unit and other node voltages are calculated as

$$V_q^{abc^k} = V_p^{abc^k} + Ze_j^{abc}\left(Y_{sh}^{abc} V_p^{abc^k} - I_j^{abc^k} \right) \quad (7)$$

Where

$V_q^{abc^k}$, $V_p^{abc^k}$ are the voltage vectors of phases for p^{th} and q^{th} nodes respectively in k^{th} iteration

$$Ze_j^{abc} = \begin{bmatrix} ze_j^{aa} & ze_j^{ab} & ze_j^{ac} \\ ze_j^{ba} & ze_j^{bb} & ze_j^{bc} \\ ze_j^{ca} & ze_j^{cb} & ze_j^{cc} \end{bmatrix}$$

$I_j^{abc^k}$ is the current vector in j^{th} branch in k^{th} iteration

These calculations will be carried out till the voltage at each bus is within the specified limits. At this point the voltages at each node, and the currents flowing in all line segments are known, which are used to find the power losses in each line segment.

Therefore the real and reactive power losses in the line between nodes p and q may be written as:

$$S_j^{abc} = \left(V_p^{abc} - V_q^{abc} \right)\left(I_j^{abc} \right)^* \quad (8)$$

Where s_j^{abc} is a vector of power loss with three, two or single phase V_q^{abc} and V_p^{abc} are voltage vector of three phases at nodes p and q

I_j^{abc} is the branch current vector of three phases for the section connected in between p^{th} and q^{th} nodes

II. SOLUTION METHODOLOGY

Feeder reconfiguration is performed by opening/closing two types of switches; tie and sectionalizing switches. A whole feeder or part of a feeder may be served from another feeder by closing a tie switch linking the two while an appropriate sectionalizing switch must be opened to maintain radial structure. In the context of loss reduction, the problem to be addressed in this article is to identify tie and sectionalizing switches that should be closed and opened, respectively, to achieve minimize the system real losses. Genetic Algorithm (GA) is used to obtain the solution for reconfiguration of radial distribution systems to minimize the losses. The change in the losses can easily be computed from the results of two load flow studies simulating the system configurations before and after the feeder reconfiguration.

III. IMPLEMENTATION OF GENETIC ALGORITHM

A. Chromosome Coding Strategy

Encoding strategies are methods, which effect genetic operations especially during crossover. Most of available GA applications in power systems are simply employing GA and no special attention has been put on the characteristic of the solved problem, modeling and solving technique. In fact, the most critical problem in applying a GA is to find a suitable encoding method for chromosomes in the problem domain. A good choice of chromosome coding will make the search easy by limiting the search space. A poor choice will result in a

large search space and divergence. There are two basic principles for choosing a GA coding: The first principle is to select encoding such that the building blocks of the underlying designer small and relatively unrelated to building blocks at other positions. The second principle states that the user should select the smallest alphabet that permits an expansion of the design so that the number of exploitable schemes is maximized. In the following section, by making use of radial feature of distribution systems, a GA based algorithm is proposed.

B. Shorten the Length of the Chromosome

To maintain continuous power supply to all the loads, the following set of rules to be adopted for selection of switches. Rule 1: All switches that do not belong to any loop are to be closed.
Rule 2: All switches connected to the sources are to be closed.
Rule3: Sectionalizing switches, those lie on primary side of the tie switches, are taken as opening options of the initial configuration.
Rule4: Selection of sectionalizing switches to be opened is done by taking any one switch among the available set of switches for a particular tie switch closed.

C. Genetic Operations

In this algorithm, Roulette wheel selection method is employed. This method has more advantages compared to random selection. Since here selection is implemented as a linear search through Roulette wheel with slots weighted in proportion to string fitness values. Here chromosomes are ranked in ascending order according to their fitness values. The individual with best fitness are adopted the individual with best fitness are obtained for next generation. In this proposed algorithm crossover operations are defined as to exchange between templates while mutation operations are restricted within the template.

D. Reproduction

For selecting the parents to perform crossover, Roulette wheel selection has been adopted as it gives best results than random selection. In this process fitness of each string is calculated, sorted in ascending order and then according to their fitness, parents are selected to crossover.

E. Crossover

The uniform crossover process randomly selects two parents to exchange the bits of chromosome with a crossover rate P_c i.e. a random number in the range [0 1] is generated. If that value is less than P_c, a mask is generated with the length equal to string length. If bit of mask is 1 particular bit is exchanged between two parents.

Before crossover	After crossover
10101	11110
01110	00101
Mask	01011

F. Mutation

Mutations are restricted in one string. Mutation is the occasional random alteration of value of string position i.e., changing a 1 to 0 and vice versa. In the proposed method, a random number between 0 and 1 is generated if that number is less than P_m and bits of particular string are altered. Of course, loops might share branches in complicated power distribution system and templates may overlap, these overlaps are eliminated in this algorithm. In this situation, feasible solutions produced during GA operation and mute individual will be discarded.

G. Fitness

The fitness should be capable of reflecting the objective and directing the search towards optimal solution. Load flow calculation is performed to obtain total active power loss. Reciprocal value of total active power loss is proposed as fitness function to obtain optimal active power loss. So maximization of fitness function of the GA can be written as

$$Maximize \quad F = \frac{1}{1+f} \qquad (9)$$

$$Where \quad f = \sum_{j=1}^{nb} P_{loss\,j}^{abc}$$

IV. ILLUSTRATIVE EXAMPLES

The performance of the proposed method is evaluated on two test systems of unbalanced radial distribution system to minimize the power loss by network reconfiguration. The proposed method is illustrated with two test systems consisting of 19 node and 25 node unbalanced radial distribution systems.

A. Example - 1

The 11 kV, 19 node unbalanced radial distribution system with base reconfiguration is shown in Fig. 2. Base MVA for 19 node unbalanced radial distribution system is 1 MVA. The line, load and tie switch data are given in appendix A1. The normally opened switches are s19 and s20. The GA control parameters selected are length of chromosome (12), population size (20), cross over probability (0.8), and mutation probability (0.04).

Fig. 2 Single line diagram of 19 node URDS before network reconfiguration

Voltage profile and summary of test results of 19 node URDS before and after network reconfiguration are given tables 1 and 2 respectively. From tables 1 and 2, it has been observed that the minimum voltage in phases A, B, C are improved from 0.9516, 0.9498 and 0.9505 to 0.9703, 0.9694

and 0.9690 p.u and the active power loss in phases of A, B and C are reduced from 4.45, 4.45 and 4.56 kW to 2.83, 2.53 and 2.86 kW respectively. Hence, there is an improvement in the minimum voltage and reduction in power loss when compared with the before network reconfiguration and after network reconfiguration.

Fig. 7 Total Active Power loss Vs Generation number of 25 node URDS

Comparison of test results of the proposed method for 19 node and 25 node URDS with the excising methods are given in table 5. The proposed method has been compared with exciting methods of Shirmohammadi and Hong's method [4] and Goswami and Basu's method [5] and results are presented in Table 5. From table 3.10 the effectiveness of the proposed method compared with number of switching operation and loss reduction with two existing methods. The total active power loss reduction has been improved after network reconfiguration. The number of switching operations was less for the proposed method when compared with the existing methods. Hence the proposed method is superior when compared with the existing methods.

VI. CONCLUSION

The results demonstrate the effectiveness of the proposed algorithm. In addition to power loss reduction, voltage profile is also improved by the proposed method. The objective function of this paper has been shown that genetic algorithm can be used to find the configuration of the unbalanced distribution networks which minimizes overall power losses of the distribution system. It has been found that the proposed method switching options are lesser than the existing methods. The effectiveness of proposed method has been tested on two unbalanced radial distribution systems.

TABLE V
COMPARISON OF TEST RESULTS FOR 19 AND 25 NODE URDS WITH THE EXISTING METHODS

Methods	19 node URDS		25 node URDS	
	No of switching operation	Loss reduction (kW)	No of switching operation	Loss reduction (kW)
Shirmohammadi and Hong method [4]	6	5.19	5	16.63
Goswami and Basu method [5]	6	5.19	5	16.63
Proposed Method	6	5.21	3	16.63
